Abstract: The vegetation ecosystem of the Qinghai–Tibet Plateau in China, considered to be the "natural laboratory" of climate change in the world, has undergone profound changes under the stress of global change. Herein, we analyzed and discussed the spatial-temporal change patterns and the driving mechanisms of net primary productivity (NPP) in the Qinghai–Tibet Plateau from 2000 to 2015 based on the gravity center and correlation coefficient models. Subsequently, we quantitatively distinguished the relative effects of climate change (such as precipitation, temperature and evapotranspiration) and human activities (such as grazing and ecological construction) on the NPP changes using scenario analysis and Miami model based on the MOD17A3 and meteorological data. The average annual NPP in the Qinghai–Tibet Plateau showed a decreasing trend from the southeast to the northwest during 2000–2015. With respect to the inter-annual changes, the average annual NPP exhibited a fluctuating upward trend from 2000 to 2015, with a steep increase observed in 2005 and a high fluctuation observed from 2005 to 2015. In the Qinghai–Tibet Plateau, the regions with the increase in NPP (change rate higher than 10%) were mainly concentrated in the Three-River Source Region, the northern Hengduan Mountains, the middle and lower reaches of the Yarlung Zangbo River, and the eastern parts of the North Tibet Plateau, whereas the regions with the decrease in NPP (change rate lower than –10%) were mainly concentrated in the upper reaches of the Yarlung Zangbo River and the Ali Plateau. The gravity center of NPP in the Qinghai–Tibet Plateau has moved southwestward during 2000–2015, indicating that the increment and growth rate of NPP in the southwestern part is greater than those of NPP in the northeastern part. Further, a significant correlation was observed between NPP and climate factors in the Qinghai–Tibet Plateau. The regions exhibiting a significant correlation between NPP and precipitation were mainly located in the central and eastern Qinghai–Tibet Plateau, and the regions exhibiting a significant correlation between NPP and temperature were mainly located in the southern and eastern Qinghai–Tibet Plateau. Furthermore, the relative effects of climate change and human activities on the NPP changes in the Qinghai–Tibet Plateau exhibited significant spatial differences in three types of zones, i.e., the climate change-dominant zone, the human activity-dominant zone, and the climate change and human activity interaction zone. These research results can provide theoretical and methodological supports to reveal the driving mechanisms of the regional ecosystems to the global change in the Qinghai–Tibet Plateau.

Spatial and temporal change patterns of net primary productivity and its response to climate change in the Qinghai–Tibet Plateau of China from 2000 to 2015. *Journal of Arid Land*, 12(1): 1–17. <https://doi.org/10.1007/s40333-019-0070-1>

1 Introduction

Net primary productivity (NPP) denotes the total amount of organic dry matter accumulated by green plants with respect to the unit time and area (Bhaskar, 2000; Rachhpal et al., 2007; Jiao et al., 2018). NPP is the residual part of the total amount of organic matter produced by photosynthesis after the elimination of autotrophic respiration. As the core content of the carbon budget and climate change research, NPP serves as an important indicator to determine the ecosystem health and sustainable development level (Alexander et al., 2007; Zhang et al., 2014; Leandro et al., 2019). Therefore, analyzing and discussing the spatial-temporal change patterns and the driving mechanisms of NPP in a regional vegetation ecosystem not only are of significance to understand the response of this ecosystem to climate change, but also can provide a scientific basis for ecological environment protection, plant yield estimation, resource exploitation, effective management of natural resources, and formulation of the corresponding social and economic development strategies (Sun et al., 2014).

Currently, NPP research is conducted abroad using climate models (such as the BIOME-BioGeoChemical Cycle (BIOME-BGC) model, Carnegie-Ames-Stanford Approach (CASA) model and Global Production Efficiency (GLO-PEM) model) and remote sensing technology, whereas domestic scholars have utilized foreign empirical models (such as the Ball–Berry model and Boreal Ecosystem Productivity Simulator (BEPS) model) to comprehensively study the NPP in different spatial scale zones of China, such as northwest region, northeast region and southwest region (Mao et al., 2015; Guo et al., 2017; Han et al., 2018; Jiao et al., 2018; Xu et al., 2019; Zhu et al., 2019). Furthermore, the driving mechanisms on the response of NPP to climate change differ because of the differences in data sources, research areas and spatial-temporal scales (Chandrasekaran and Swamy, 2002; Travis et al., 2015). NPP globally increased from 1980 to 2000; however, the reasons varied in different regions (Li et al., 2018; Ji et al., 2019). Under the background of global change, climate in China has undergone significant changes, and the NPP of terrestrial vegetation exhibited an increasing trend (Chirici et al., 2007; Gao et al., 2018; Wang and Li, 2018; Wang et al., 2018). Climate change weakens the stress of hydrothermal conditions on vegetation growth. However, the response of vegetation NPP in China to climate change shows obvious regional differences (Guo et al., 2017; Li et al., 2017; Wang et al., 2017; Wang et al., 2018; Fatemeh et al., 2019). Therefore, further studies are required to investigate the driving mechanisms of NPP under the stress of global change in different regions (Edward et al., 2013).

The unique geographical location, altitude, climate and geomorphological conditions of the Qinghai–Tibet Plateau in China result in various climatic and ecosystem types. As a special geographic unit, the Qinghai–Tibet Plateau exhibits an important role in regulating and indicating global change; it is considered to be the "natural laboratory" for studies of climate change in the world (Haberl et al., 2004; Huang et al., 2008; Sun et al., 2014; Wang et al., 2016). Although some previous studies have used conventional analysis methods (such as the correlation analysis model) to investigate the NPP change patterns in the Qinghai–Tibet Plateau, the relationships between NPP and climate factors and the relative effects of climate change and human activities on the NPP changes remain unclear (Sun et al., 2014; Huang et al., 2018; Jeremy et al., 2018; Sunil et al., 2019). Further, the "gravity center" concept, which indicates the point at which the force of gravity present on each part of an object exerts a resultant force, is derived from physics (Liu et al., 2011). However, in geography, the "gravity center" concept has been extensively applied to population, economy, food, land use, ecological environment, regional development and other fields (Liu et al., 2011). The spatial variation of the gravity center can better reflect the

variation degree and trend of geographical phenomena.

Therefore, in this study, a gravity center model was introduced to analyze the spatial and temporal change patterns and the driving mechanisms of NPP in the Qinghai–Tibet Plateau from 2000 to 2015 in combination with the conventional analysis methods. Furthermore, the relative effects of climate change and human activities on the NPP changes were also quantitatively distinguished. This study provides data and theoretical support to reveal the evolution patterns of the ecosystems in the Qinghai–Tibet Plateau and the response mechanisms of the ecosystems to global change.

2 Study area and data sources

2.1 Study area

The Qinghai–Tibet Plateau extends from the Pamir Plateau and Karakorum Mountains in the west to the Hengduan Mountains in the east and from the Himalaya Mountains in the south to the Kunlun Mountains, Altun Mountains and Qilian Mountains in the north (26°00′12″–39°46′50″N, 73°18′52″–104°46′59″E). The plateau exhibits a total area of approximately 2.5×10^7 km² and an average altitude of 4000 m or more and is referred to as "the third pole". The annual mean temperature is lower than 0°C in the hinterland of the plateau; furthermore, the temperature decreases with increasing altitude and latitude. The mean annual precipitation decreases from 2000 mm in the southeast to 50 mm in the hinterland of the plateau (Sun et al., 2014). In summer, abundant precipitation can be observed in most regions of the southeastern plateau because of the influence of the monsoon and humid airflow from the southwest Indian Ocean. In winter, strong winds (lasting for up to 200 d in some places) and scarce precipitation can be observed because of the influence of the dry westerlies in the plateau. Further, complex and diverse vegetation landscape types, including forests, meadows, grasslands and deserts, appear successively in the horizontal belt spectrum of the Qinghai–Tibet Plateau, and the climate gradually changes from the marine wet type in the southeast to the continental arid type in the hinterland of the plateau (Yang et al., 2015).

2.2 Data sources

The NPP during 2000–2015 obtained from the MOD17A3 dataset is available at <https://lpdaac.usgs.gov/>. The spatial and temporal resolutions were 1 km and 1 a, respectively. The data (including the daily precipitation and mean daily temperature) of 229 meteorological stations in the Qinghai–Tibet Plateau and its surrounding areas, were obtained from the China Meteorological Data Network (<http://data.cma.cn/>). The MOD17A3 data were mosaicked and reprojected using the MODIS Projection Tool. Further, the annual mean temperature and annual precipitation were interpolated into grids with a spatial resolution of 1 km×1 km using the Cokriging method in ArcGIS 10.3. Considering the uneven spatial distributions of the meteorological stations in the western Qinghai–Tibet Plateau, we constructed the interpolated stations for the entire Qinghai–Tibet Plateau based on the China Meteorological Forcing Dataset (<http://westdc.westgis.ac.cn/>), especially in the central and western regions. Locations of the meteorological and interpolated stations in the Qinghai–Tibet Plateau and its surrounding areas are shown in Figure 1.

3 Methods

3.1 Change trend analysis

Linear regression analysis can be used to eliminate the influence of extreme climate in specific years to some extent (Tian et al., 2019). Therefore, this study adopted linear regression analysis to analyze the time series change trend of NPP, which can be calculated as follows:

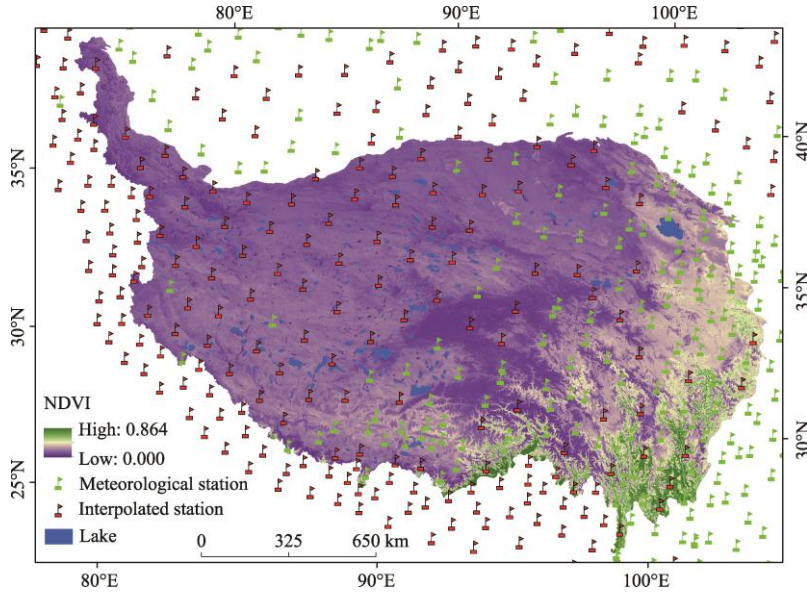

Fig. 1 Spatial distributions of the average annual NDVI (during 2000–2015) in the Qinghai–Tibet Plateau and locations of the meteorological stations and interpolated stations in the Qinghai–Tibet Plateau and the surrounding areas

$$\theta_{\text{slope}} = \frac{n \times \sum_{i=1}^n i \times \text{NPP}_i - \sum_{i=1}^n i \sum_{i=1}^n \text{NPP}_i}{n \times \sum_{i=1}^n i^2 - \left(\sum_{i=1}^n i \right)^2}, \quad (1)$$

where θ_{slope} denotes the gradient of change trend for vegetation NPP; n is the number of years or the whole study period (16 a); i is a variable of time and can be given as $i=1, 2, 3, \dots, 16$; and NPP_i is the NPP in the i^{th} year. The change rate of NPP can be given as follows:

$$\text{NPP}_{\text{cr}} = \frac{\theta_{\text{slope}}}{\text{NPP}_{\text{mean}}} \times n \times 100\%, \quad (2)$$

where NPP_{cr} refers to the change rate of NPP in percentage (%); NPP_{mean} is the average annual NPP during the period 2000–2015; and n is the number of years.

3.2 Correlation analysis

Correlation analysis is mainly used to indicate the correlation degree and direction between variables (Huang et al., 2008; Liu et al., 2011; Li and Zhao, 2013; Wang et al., 2016). In this study, we analyzed the correlation and significance level between NPP and climate factors (temperature and precipitation) using the Pearson's correlation coefficient based on pixels at confidence levels of 0.05 and 0.01. The correlation coefficient, partial correlation coefficient and complex correlation coefficient were calculated as Equations 3–5, respectively:

$$r_{x,y} = \frac{\sum_{i=1}^n (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^n (x_i - \bar{x})^2 \sum_{i=1}^n (y_i - \bar{y})^2}}, \quad (3)$$

$$r_{xy_1, y_2} = \frac{r_{x, y_1} - r_{x, y_2} r_{y_1, y_2}}{\sqrt{1 - r_{x, y_2}^2} \sqrt{1 - r_{y_1, y_2}^2}}, \quad (4)$$

$$R_{x,y_1y_2} = \sqrt{1 - (1 - r_{x,y_1}^2)(1 - r_{xy_2,y_1}^2)}, \quad (5)$$

where $r_{x,y}$ is the correlation coefficient of variables i and j ; x_i and y_i denote the values of variables x and y in the i^{th} year, respectively; and \bar{x} and \bar{y} denote the average values of variables i and j , respectively. The value of r ranges from -1 to 1 . A value greater than 0 indicates a positive correlation between variables i and y , while a value lower than 0 indicates a negative correlation. In Equations 4 and 5, r_{xy_1,y_2} refers to the partial correlation coefficient of x and y_1 after fixing y_2 ; r_{x,y_1} refers to the correlation coefficient of variables x and y_1 ; r_{x,y_2} refers to the correlation coefficient of variables x and y_2 ; r_{y_1,y_2} refers to the correlation coefficient of variables y_1 and y_2 ; R_{x,y_1y_2} refers to the complex correlation coefficient of variables x , y_1 and y_2 ; and r_{xy_2,y_1} refers to the partial correlation coefficient of variables x and y_2 after fixing y_1 . In addition, the T test and F test were used to analyze the significance of the partial correlation coefficient and complex correlation coefficient. The formula can be given as follows:

$$T = \frac{r_{xy_1,y_2}}{\sqrt{1 - r_{xy_1,y_2}^2}} \times \sqrt{n - m - 1}, \quad (6)$$

$$F = \frac{R_{x,y_1y_2}^2}{1 - R_{x,y_1y_2}^2} \times \frac{n - m - 1}{m}, \quad (7)$$

where n denotes the number of samples and m denotes the number of variables.

3.3 Gravity center model

In a gravity center model, z_i is considered as the attribute value of the number i plane space unit (grid) (Liu et al., 2011). When the Cartesian coordinate is set as (x_i, y_i) , the spatial mean of the region comprising three plane space units (grids) is defined as a Cartesian coordinate point (\bar{x}, \bar{y}) and can be expressed as:

$$\bar{x} = \frac{\sum_{i=1}^n z_i x_i}{\sum_{i=1}^n z_i}, \quad (8)$$

$$\bar{y} = \frac{\sum_{i=1}^n z_i y_i}{\sum_{i=1}^n z_i}. \quad (9)$$

With respect to this spatial phenomenon, an unbalanced distribution or "deviation of the gravity center" can be observed when the regional gravity center of a spatial phenomenon significantly differs from the geometric center. The deviation direction of the gravity center is toward the "high-density" area of the spatial phenomenon, and the deviation distance of the gravity center can be used to describe the degree of unbalanced distribution. Further, the mitigation trajectory of the gravity center in different periods can reflect the evolution process of the spatial phenomenon distribution. The formulas for obtaining the mitigation direction and mitigation distance of the gravity center are given as follows:

$$\theta = \arctan\left(\frac{y_{t+m} - y_t}{x_{t+m} - x_t}\right) + m, \quad (10)$$

$$d_m = \sqrt{(x_{t+m} - x_t)^2 + (y_{t+m} - y_t)^2}, \quad (11)$$

where θ and d_m refer to the mitigation direction and mitigation distance of the gravity center, respectively; y_{t+m} and y_t refer to the latitude coordinates of the gravity center in time $t+m$ and time t , respectively; and x_{t+m} and x_t refer to the longitude coordinates of the gravity center in time $t+m$

and time t , respectively.

3.4 Miami model

In this study, the Miami model was adopted to estimate the potential vegetation NPP. This model based on Liebig's minimum method was the first NPP estimation model and has been widely adopted at home and abroad. It includes a function of the annual mean temperature and annual precipitation (Mao et al., 2015).

$$NPP_{climate} = \min \left\{ \left(1 + \frac{3000}{\exp(1.315 - 0.119T)} \right), (3000[1 - \exp(-0.000664P)]) \right\}, \quad (12)$$

where $NPP_{climate}$ is the potential vegetation NPP; T refers to the annual mean temperature ($^{\circ}\text{C}$); and P refers to the annual precipitation (mm).

3.5 Method for distinguishing the relative effects of climate change and human activities on the NPP changes

Climate change and human activities are the main factors that affected the dynamic changes in vegetation NPP. According to the study of Mao et al. (2015), the relative effects of climate change and human activities on the NPP changes could be quantitatively evaluated and distinguished. In this study, three types of NPP changes were identified and obtained. The first type (actual NPP (NPP_{actual})), derived from MOD17A3, was based on the combined effects of climate change and human activities; the second type (potential NPP ($NPP_{climate}$)), obtained from the Miami model, was based on the effects of climate change; and the third type (human activity-related NPP (NPP_{human})) was the residual of the $NPP_{climate}$ and NPP_{actual} , which can be mainly attributed to human activities such as grazing and ecological construction.

Further, we calculated the change trends of $NPP_{climate}$ and NPP_{human} (K_c and K_h , respectively) to assess and distinguish the relative effects of climate change and human activities on the NPP changes. When K_c is positive, climate change is conducive to vegetation restoration. In contrast, climate change exacerbates vegetation degradation when K_c is negative. Human activities exacerbate vegetation degradation when K_h is positive, whereas human activities are conducive to vegetation restoration when K_h is negative. The change trend of NPP_{actual} (K_a) could indicate either vegetation restoration or degradation. When K_a is positive, the vegetation is observed to undergo restoration, whereas the vegetation is observed to undergo a degradation process when K_a is negative. As shown in Table 1, six possible scenarios for the NPP changes have been defined (Sun et al., 2014; Wang et al., 2018).

Table 1 Relative effects of climate change and human activities on the NPP changes

Change trend of NPP	Scenario	K_c	K_h	Relative effects of climate change (%)	Relative effects of human activities (%)
$K_a > 0$ (vegetation restoration)	Scenario 1	>0	>0	100	0
	Scenario 2	<0	<0	0	100
	Scenario 3	>0	<0	Combined effects	Combined effects
$K_a < 0$ (vegetation degradation)	Scenario 4	>0	>0	0	100
	Scenario 5	<0	<0	100	0
	Scenario 6	<0	>0	Combined effects	Combined effects

Note: K_a refers to the change trend of actual NPP (NPP_{actual}); and K_c and K_h refer to the change trends of potential NPP ($NPP_{climate}$) and human activity-related NPP (NPP_{human}), respectively.

4 Results

4.1 Spatial variation characteristics of NPP

4.1.1 Spatial distribution patterns of average annual NPP during 2000–2015

Figure 2 denotes that the spatial distribution of average annual NPP significantly differed in the Qinghai–Tibet Plateau during 2000–2015. Generally, a decreasing trend can be observed from the southeast to the northwest; this was related to the spatial and temporal distributions of the

regional hydrothermal and climate conditions. During the study period, the average annual NPP in the Qinghai–Tibet Plateau was $167.52 \text{ g C}/(\text{m}^2\cdot\text{a})$. Further, the average annual NPP for majority of the study area, such as the North Tibet Plateau, the middle and upper reaches of the Yarlung Zangbo River, and the Ali Plateau, was lower than $400.00 \text{ g C}/(\text{m}^2\cdot\text{a})$. A high-value zone of average annual NPP can be observed in the southeastern part of the Qinghai–Tibet Plateau. The regions exhibiting an average annual NPP of greater than $600.00 \text{ g C}/(\text{m}^2\cdot\text{a})$ were mainly distributed in the southern part of the Hengduan Mountains. The regions with an average annual NPP of $200.00\text{--}400.00 \text{ g C}/(\text{m}^2\cdot\text{a})$ were mainly distributed in the West Sichuan Plateau. A decreasing trend for the average annual NPP was observed from the south to the north and from the west to the east in the Hengduan Mountains. The regions exhibiting high average annual NPP values in the Hengduan Mountains were mainly concentrated in the southern part, which can be attributed to the vegetation type, topography and climate in this region.

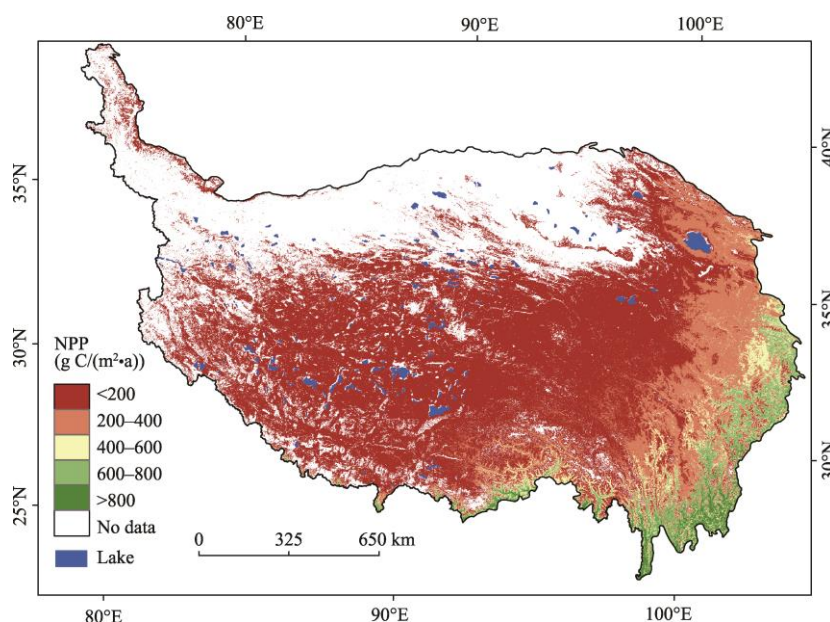

Fig. 2 Spatial distributions of average annual NPP (net primary productivity) in the Qinghai–Tibet Plateau during 2000–2015

4.1.2 Spatial change patterns of average annual NPP

The change rate of NPP in the Qinghai–Tibet Plateau from 2000 to 2015 was analyzed. During the study period, the regions exhibiting the change rate of NPP in the range of $10\%\text{--}30\%$ in the Qinghai–Tibet Plateau were the largest, accounting for 45.55% of the whole study area, followed by the regions exhibiting the change rate of NPP in the range from -10% to 10% , accounting for 33.39% (Fig. 3). The regions with the change rate of NPP lower than -30% were the smallest, only accounting for 0.91% . These results denote an increasing trend with respect to the inter-annual changes of NPP in the Qinghai–Tibet Plateau from 2000 to 2015, indicated by the stable ($-10\% < \text{change rate of NPP} < 10\%$) and increasing (change rate of NPP $> 10\%$) regions, accounting for 94.20% of the total study area.

Figure 4 shows that the stable regions with the change rate of NPP in the range from -10% to 10% were mainly distributed in the eastern and southern parts of the Qinghai–Tibet Plateau, including the northern Hengduan Mountains and the southern Ali Plateau. The regions exhibiting the change rate of NPP greater than 30% were mainly distributed in the eastern part of the North Tibet Plateau, the lower reaches of the Yarlung Zangbo River and the middle of the Hengduan Mountains. The regions exhibiting the change rate of NPP in the range of $10\%\text{--}30\%$ were the most widely distributed and mainly concentrated in the Three-River Source Region, the northern Hengduan Mountains, the middle and lower reaches of the Yarlung Zangbo River, and the middle

and eastern parts of the North Tibet Plateau. The regions with NPP reduction (change rate of NPP lower than -10%) were mainly distributed in the upper reaches of the Yarlung Zangbo River and the Ali Plateau.

Fig. 3 Area percentages of regions with different grades in the change rate of NPP in the Qinghai-Tibet Plateau during 2000–2015

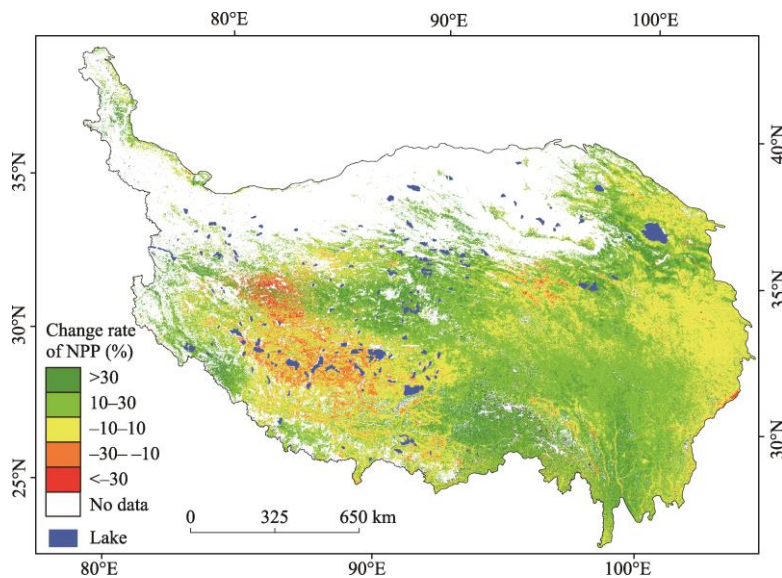

Fig. 4 Spatial distributions of regions with different grades in the change rate of NPP in the Qinghai-Tibet Plateau during 2000–2015

The gravity center could effectively denote the imbalance and bias of NPP changes with respect to the spatial distribution. In this study, the gravity centers of NPP for each year and average NPP of the total study period (16 a) were calculated (Fig. 5). It can be seen that the gravity centers of NPP were mainly concentrated in the southeastern part of the Qinghai-Tibet Plateau. This indicated that the total NPP in the southeastern part of the Qinghai-Tibet Plateau was larger when compared with that in the northwestern part. This result was consistent with the conclusion obtained from Figure 2 that the average annual NPP decreased from the southeast to the northwest in the Qinghai-Tibet Plateau.

In this study, we established the polar coordinate system by adopting the mean NPP gravity center (during 2000–2015) in the study area as the origin (representing the average state) and using the migration distance and migration angle of the NPP gravity center to the origin as the

polar radius and polar angle, respectively, to further analyze the spatial distribution patterns of the gravity centers for NPP in the Qinghai–Tibet Plateau. The number of the NPP gravity centers in different quadrants of the coordinate system and its percentage were estimated. The results shown in Figure 6 denoted that 37.50% of the NPP gravity centers were located in the southwest quadrant, which were followed by those in the northeast quadrant with a proportion of 25.00%. This indicated that the increment and growth rate of NPP in the southwestern and northeastern parts of the Qinghai–Tibet Plateau were relatively large during the study period. In addition, the sum of the gravity center number in the two aforementioned quadrants accounted for 62.50% of the total gravity center number. Further, the proportions of the NPP gravity centers in the northwest and southeast quadrants were relatively small at 18.75%. Thus, we divided the study area into two parts based on the coordinate axis. The gravity center number of NPP in the northern half quadrant (43.75%) was slightly smaller than that in the southern half quadrant (56.25%). This indicated that the increment and growth rate of NPP in the southern part of the Qinghai–Tibet Plateau were larger than those in the northern part during 2000–2015. Meanwhile, the gravity centers of NPP had larger migration distances when compared with the origin in 2002, 2003, 2005 and 2014, which indicated a significant increment of NPP in the northeastern and southwestern parts of the Qinghai–Tibet Plateau. In 2006, 2007 and 2008, the migration distances of the gravity center of NPP were smaller, implying that the changes in NPP in each parts of the Qinghai–Tibet Plateau were relatively consistent in these three years.

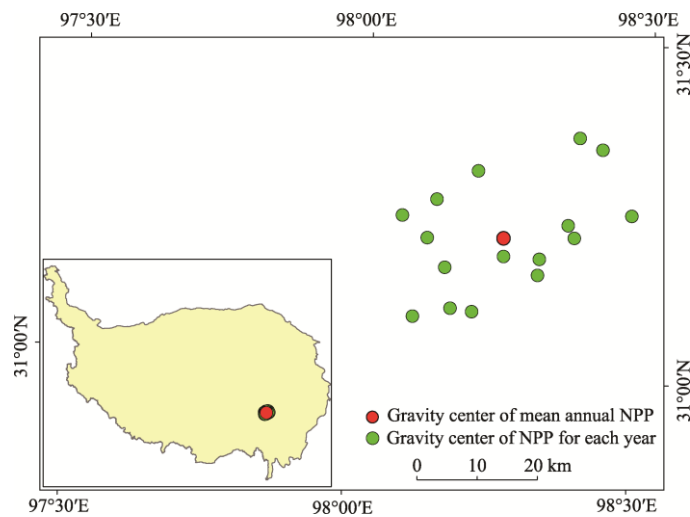

Fig. 5 Distributions of the gravity centers of NPP in the Qinghai–Tibet Plateau during 2000–2015

Further, we analyzed the migration directions of the NPP gravity center at different temporal scales during 2000–2015 to explore the spatial variations of the gravity center of NPP in the Qinghai–Tibet Plateau. Considering the influences of extreme climate and other factors on the annual change in vegetation NPP, we adopted three temporal scales (3, 5 and 16 a) to analyze the migration directions of the gravity center of NPP in the Qinghai–Tibet Plateau. Figure 7 denotes that the gravity center of NPP moved eastward from 2000–2002 to 2003–2005, indicating that the increment and growth rate of NPP in the eastern part of the study area were higher than those in the western part. The gravity center of NPP during 2006–2008 moved toward the southwest direction when compared with that during 2003–2005, indicating that the growth rate of NPP in the southwestern part was greater than that in the northeastern part. Further, when compared with the gravity center of NPP during 2006–2008, the gravity centers during 2009–2011 and 2012–2015 moved westward, suggesting that the increment of NPP in the western part of the Qinghai–Tibet Plateau was larger than that in the eastern part during 2009–2015. On a 5-a temporal scale, the gravity center of NPP in the Qinghai–Tibet Plateau initially moved to the southeast direction from 2000–2004 to 2005–2009 and subsequently moved to the west direction from 2005–2009 to

2010–2015. Thus, in the Qinghai–Tibet Plateau, the increments of NPP in the southeastern part during 2005–2009 and in the western part during 2010–2015 were greater than those in the northwestern part during 2000–2004 and in the eastern part during 2005–2009, respectively. Generally, during the period 2000–2015, the gravity center of NPP in the Qinghai–Tibet Plateau moved southwestward, indicating that the increment and growth rate of NPP in the southwestern part were larger than those in the northeastern part.

Fig. 6 Polar coordinates of the gravity centers of NPP in the Qinghai–Tibet Plateau during 2000–2015. The green dots indicate the gravity centers.

Fig. 7 Migration trajectory of the gravity centers of NPP in the Qinghai–Tibet Plateau during 2000–2015 at different temporal scales (3-, 5- and 16-a temporal scales)

4.2 Inter-annual variations of average annual NPP

From 2000 to 2015, the average annual NPP in the Qinghai–Tibet Plateau showed an increasing trend with a slight fluctuation (Fig. 8). The fluctuation range was 0.00–32.88 g C/(m²·a). During the study period, the maximum NPP value was 182.95 g C/(m²·a) in 2013, followed by 180.88 g C/(m²·a) in 2006, whereas the minimum value was 150.07 g C/(m²·a) in 2000. Before 2005, the average annual NPP in the Qinghai–Tibet Plateau was less than 160.00 g C/(m²·a) and the increase trend was minimal. After 2005, however, the average annual NPP increased significantly,

with the mean value of 170.00 g C/(m²·a). In 2006 and 2013, the average annual NPP values were 180.88 and 182.95 g C/(m²·a), respectively. This increasing trend of average annual NPP mainly resulted from the implementation of the ecological projects of "returning farmland to grassland" and "returning grazing land to grassland".

Fig. 8 Inter-annual variations of average annual NPP in the Qinghai-Tibet Plateau during 2000–2015

4.3 Correlation analyses of NPP with precipitation and temperature

4.3.1 Changes of climate factors during 2000–2015

As shown in Figure 9, the annual precipitation of the Qinghai-Tibet Plateau during 2000–2015 ranged from 379.36 to 541.10 mm. In addition, the average annual precipitation was 490.65 mm during the study period, with the maximum value observed in 2010 and the minimum value in 2007. During the study period, a slight decrease was observed in the annual precipitation in the Qinghai-Tibet Plateau; further, the average annual precipitation decreased from the southeast to the northwest with respect to the spatial distribution. During 2000–2015, the annual mean temperature significantly increased in the Qinghai-Tibet Plateau, ranging from 0.67°C (2002) to 2.98°C (2007). Meanwhile, the mean annual temperature during the study period was 1.48°C.

Fig. 9 Inter-annual variations of (a) annual precipitation and (b) annual mean temperature in the Qinghai-Tibet Plateau during 2000–2015

4.3.2 Correlation analyses of NPP with precipitation and temperature

Because the influences of precipitation and temperature on the NPP are often intersectional and dependent, the partial correlation coefficient and complex correlation coefficient between NPP and precipitation and between NPP and temperature in the Qinghai-Tibet Plateau during 2000–2015 were calculated pixel by pixel (Fig. 10).

As shown in Figure 10a, the partial correlation coefficient between NPP and annual precipitation ranged from −0.86 to 0.91. The regions exhibiting positive partial correlation

coefficients between NPP and annual precipitation accounted for 54.57% of the total study area and were mainly distributed in the central and northeastern of the Qinghai–Tibet Plateau. In contrast, the regions with negative partial correlation coefficients between NPP and annual precipitation were mainly concentrated in the southern part of the North Tibet Plateau, the upper reaches of the Yarlung Zangbo River Basin and the Ali Plateau.

Fig. 10 Partial correlation coefficient, multiple correlation coefficient and significant test results of NPP with precipitation and temperature in the Qinghai–Tibet Plateau. (a), partial correlation coefficients between NPP and precipitation; (b), significance of T test for the partial correlation coefficients between NPP and precipitation; (c), partial correlation coefficients between NPP and temperature; (d), significance of T test for the partial correlation coefficients between NPP and temperature; (e), complex correlation coefficients between NPP and climate factors (precipitation and temperature); (f), significance of F test for the complex correlation coefficients between NPP and climate factors. Coeff., correlation coefficient.

As shown in Figure 10c, the regions with positive partial correlation coefficients between NPP and temperature accounted for 47.13% of the total study area and were mainly distributed in the eastern and southern parts of the Qinghai–Tibet Plateau. Meanwhile, the regions with negative partial correlation coefficients accounted for 52.87% of the total study area and were mainly

distributed in the western part of the Three-River Source Region, the upper reaches of the Yarlung Zangbo River Basin, the southern part of the Hengduan Mountains and its surrounding areas. In addition, the significances of partial correlation coefficients between NPP and precipitation and between NPP and temperature were evaluated using the T tests.

The results shown in Figures. 10b and d revealed that for the partial correlation coefficients between NPP and precipitation, 15.83% of the total study area passed the T test at $P<0.05$ level, whereas 5.34% of the whole area passed the T test at $P<0.01$ level. Thus, the regions exhibiting the extremely significant correlation between NPP and precipitation were mainly distributed in the western and eastern parts of the Three-River Source Region. For the partial correlation coefficients between NPP and temperature, approximately 12.65% of the total study area passed the T test at $P<0.05$ level, whereas 6.13% of the total area passed the T test at $P<0.01$ level. The regions with the extremely significant correlation between NPP and temperature were mainly distributed in the lower reaches of the Yarlung Zangbo River Basin.

As depicted in Figure 10e, with respect to the complex correlation coefficients between NPP and climate factors (precipitation and temperature), the coefficient values ranged from 0.00 to 0.94. In the significance of F test for the complex correlation coefficients between NPP and climate factors (Fig. 10f), approximately 16.32% of the total area passed the F test at $P<0.05$ level, whereas 5.89% of the whole study area passed the F test at $P<0.01$ level. Therefore, the regions exhibiting extremely significant complex correlations between NPP and climate factors were mainly distributed in the middle and western parts of the Three-River Source Region, the upper and lower reaches of the Yarlung Zangbo River Basin, and the West Sichuan Plateau.

4.4 Effects of climate change and human activities on the NPP changes

As shown in Figure 11, the regions with vegetation restoration (increase of NPP) accounted for 84.54% of the Qinghai–Tibet Plateau during 2000–2015, whereas the regions with vegetation degradation (decrease of NPP) occupied 15.46% of the whole study area. The regions with vegetation restoration caused by climate change accounted for 46.01% of the total study area and were mainly distributed in the western and central parts of the North Tibet Plateau and the Three-River Source Region. The regions with vegetation restoration caused by human activities accounted for 34.33% of the total study area and were mainly concentrated in the middle and lower reaches of the Yarlung Zangbo River Basin and the Hengduan Mountains. Furthermore, the combined effects of climate change and human activities resulted in a small area of vegetation restoration (3.81% of the study area), which was mainly distributed in the southern part of the Three-River Source Region. Meanwhile, the regions with vegetation degradation caused by climate change accounted for 5.05% of the total study area and were discontinuously distributed in the upper reaches of the Yarlung Zangbo River Basin and the northern part of the Hengduan Mountains. The regions with vegetation degradation caused by human activities accounted for 10.20% of the study area and were mainly concentrated in the Ali Plateau. Moreover, the regions with vegetation degradation that can be attributed to climate change and human activities were mainly distributed in the northern margin of the Yarlung Zangbo River Basin.

Thus, as shown in Figure 11, climate change was considered to be the dominant influencing factor in the A1 and A2 regions (climate change-dominant zone), the interaction zone (B) was considerably influenced by the combined effects of climate change and human activities, and the C1 and C2 regions (human activity-dominant zone) were dominated by human activities.

5 Discussion

5.1 Spatial and temporal distribution patterns of NPP

The spatial distribution of NPP in the Qinghai–Tibet Plateau showed a decreasing trend from the southeast to the northwest during 2000–2015, which was mainly influenced by the spatial distribution patterns of precipitation and temperature. Because of the Pacific Monsoon, the Hengduan Mountains in the southeastern part of the Qinghai–Tibet Plateau exhibit abundant precipitation, diverse vegetation types, broad-leaved forests, coniferous forests and shrubs, and

high vegetation NPP. The lower reaches of the Yarlung Zangbo River are affected by the warm

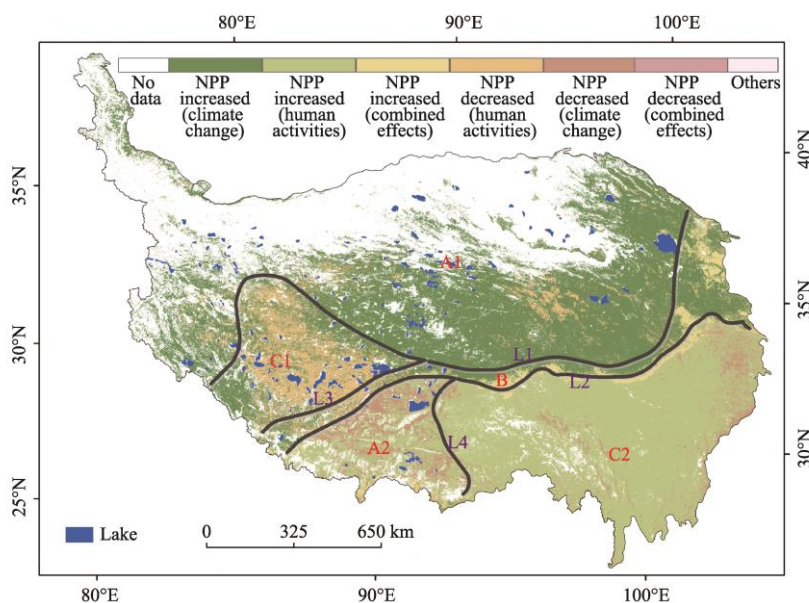

Fig. 11 Distinction of the relative effects of climate change and human activities on the NPP changes (increase or decrease). A1 and A2 refer to the regions mainly affected by climate change; B refers to the region affected by the combined effects of climate change and human activities; C1 and C2 refer to the regions mainly affected by human activities; L1, L2, L3 and L4 refer to the boundary lines for different regions.

and wet airflow in the Indian Ocean. The forest cover is high and the NPP is high in rainforests, monsoon forests and broad-leaved forests. The NPP in most areas of the northern Tibet Plateau is relatively low because of the high altitude, low temperature, low precipitation and numerous vegetation types, such as grasslands, alpine meadows and sparse shrubs (Sun et al., 2014). Deserts and desert grasslands with the lowest NPP are widespread in the Ali Plateau because of the scarcity of annual precipitation and low temperature. During 2000–2004, the average annual NPP in the Qinghai–Tibet Plateau has shown an upward trend. After 2004, the average annual NPP has shown a steep increase. This increase can be attributed to the fact that the forest lands and grasslands have been considerably restored after the implementation of the projects of "returning farmland to grassland" and "returning grazing land to grassland". The average annual NPP in the Qinghai–Tibet Plateau presented a sharp increase in 2005, with high fluctuations observed during 2005–2015.

5.2 Effects of climate factors on NPP

Based on the comprehensive analyses of NPP, precipitation and temperature, we can infer that the correlation between NPP and climate factors is significant in different regions and may be related to the altitude, climate type and vegetation type. In the central, northeastern and western parts of the Qinghai–Tibet Plateau, NPP was positively correlated with precipitation because the altitude of these regions was higher than 4000 m a.s.l. and the precipitation was low. Therefore, precipitation became the dominant factor that restricts the growth of vegetation. In addition, the grasslands and alpine meadows in these regions demonstrated a high sensitivity to precipitation (Yang et al., 2015). However, NPP was negatively correlated with precipitation in the southeastern part of the Hengduan Mountains, and the middle and lower reaches of the Yarlung Zangbo River Basin. Precipitation was abundant in these regions, so it was not the main factor that restricts the growth of vegetation. Because of the high levels of precipitation in these regions, the rainfall erosivity was high, the slope was steep and the soil erosion phenomena (freeze-thaw erosion and hydraulic erosion) were serious. In addition, the negative correlations between NPP and precipitation in some regions (especially in the Hengduan Mountains) were associated with

lower solar radiation due to increased precipitation (Liu et al., 2011). Thus, the regional vegetation ecosystem will be destroyed to a certain extent.

The regions with positive correlations between NPP and temperature were mainly distributed in the southern part of the Tibet Plateau and the northern part of the Hengduan Mountains. These regions exhibited high altitude, abundant precipitation and low temperature (restraining the growth of vegetation); therefore, the higher the temperature, the better the growth of vegetation (strong photosynthesis). The regions that exhibited negative correlations between NPP and temperature were mainly concentrated in the central and northern parts of the Qinghai–Tibet Plateau because of scarce precipitation in these regions. Although the increase in temperature was conducive to the plant photosynthesis, regional drought was exacerbated to a certain extent, inhibiting vegetation growth.

5.3 Relative effects of climate change and human activities on the NPP changes

Climate change and human activities were the main driving forces of the NPP changes in the Qinghai–Tibet Plateau. In this study, the NPP_{actual} (MOD17A3) and $NPP_{climate}$ (reversed by Miami model) were used to establish public indicators to unify the effects of climate change and human activities on the vegetation degradation or restoration to a comparable level. The results showed that the relative effects of climate change and human activities on the NPP changes in the Qinghai–Tibet Plateau exhibited significant spatial differences. The study area can be divided into three types of zones, i.e., the climate change-dominant zone, the human activity-dominant zone, and the climate change and human activity interaction zone. The climate change-dominant zone could be divided into two parts: A1 (a region with the increase in NPP induced by climate change) and A2 (a region with the decrease in NPP induced by climate change). Figure 12 shows the spatial distributions of change trend coefficients of precipitation and temperature in the Qinghai–Tibet Plateau during 2000–2015.

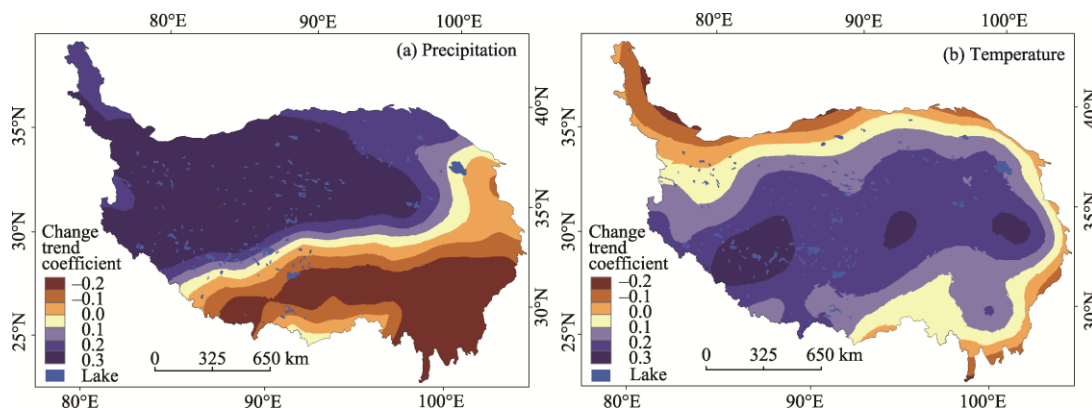

Fig. 12 Spatial distributions of change trend coefficients of (a) precipitation and (b) temperature in the Qinghai–Tibet Plateau during 2000–2015

In the A1 region, precipitation and temperature exhibited a significant increasing trend (Fig. 12) and water resources were abundant, contributing to the photosynthesis of vegetation and considerably promoting the growth of vegetation (Huang et al., 2008). In the A2 region, however, a significant increase in temperature was observed due to the scarcity of precipitation, resulting in different degrees of drought and thus destroying the regional vegetation ecosystem. The human activity-dominant zone can also be divided into two parts: C1 (a region with the decrease in NPP induced by human activities) and C2 (a region with the increase in NPP induced by human activities). Grazing and farming were the main human activities in these regions. However, with the implementation of the ecological projects of "returning farmland to grassland" and "returning grazing land to grassland", the effects of human activities on the NPP changes in different regions showed different directions (inhibition or promotion). Overgrazing and reclamation played a leading role in the C1 region, whereas ecological protection policies played an essential role in

the C2 region (Sun et al., 2014). In addition, in the Qinghai–Tibet Plateau, there existed an interaction zone (B) where the NPP changes were dominated by the combined effects of climate change and human activities. This region was a transitional zone in which human effects were gradually weakening while climate effects were gradually increasing. Thus, significant temporal and spatial differences can be observed in the relative effects of climate change and human activities on the NPP changes in the Qinghai–Tibet Plateau.

6 Conclusions

In this study, the spatial-temporal change patterns and the driving mechanism of NPP in the Qinghai–Tibet Plateau during 2000–2015 were discussed. From 2000 to 2015, the average annual NPP exhibited a decreasing trend from the southeast to the northwest over the whole Qinghai–Tibet Plateau. In terms of the inter-annual changes of NPP, a fluctuating upward trend was observed during the study period, with a steep rise observed in 2005 and a high fluctuation observed during 2005–2015. During 2000–2015, the increment and growth rate of NPP in the southwestern part were greater than those in the northeastern part. The regions that exhibited significant correlations between NPP and precipitation were mainly located in the central and eastern parts of the Qinghai–Tibet Plateau, whereas the regions that exhibited significant correlations between NPP and temperature were mainly distributed in the southern and eastern parts. The relative effects of climate change and human activities on the NPP changes in the Qinghai–Tibet Plateau exhibited significant spatial differences. The study area can be divided into three types of zones, i.e., the climate change-dominant zone, the human activity-dominant zone, and the climate change and human activity interaction zone.
